ABSTRACT

Background: Iodine is an essential micronutrient required for normal human growth and development as it is needed for the synthesis of thyroid hormones produced by thyroid glands. The sicknesses occurred due to deficiencies of iodine in the nutrition are termed iodine deficiency disorders. Urinary iodine concentration is the prime indicator of a person’s nutritional iodine status. So, the aim of this study was to assess the status of iodine deficiency based on median urinary iodine excretion.

Methods: Community based cross sectional study was carried out among purposively selected primary schools of the Dang district. All students between the age group of 6 to 12 years who were present on the day of visit were included in the study. A total 387 urine samples were collected during the period of August 2015 to September 2016.

Results: Based on median urinary iodine excretion, among total analysed samples, about 6.5% samples confirmed severe iodine deficiency, 22% samples showed moderate iodine deficiency and about 36% samples indicated mild iodine deficiency. About one third (31.3%) samples suggested optimum iodine intake. Only few samples (4.4%) revealed more than required iodine intake.

Conclusions: About one third (31.3%) of the surveyed population had adequate iodine intake while majority (64.4%) of them had inadequate iodine intake.

Keywords: Iodine intake, Iodine deficiency disorder, Median urinary iodine, School children

INTRODUCTION

Iodine is an essential micronutrient, required in minute amount of 100-150 μg daily for synthesis of the thyroid hormones, thyroxin (T₄) and triiodothyronine (T₃). It is an essential element which cannot be synthesized by our body. In areas where there is little iodine in the diet, typically remote inland areas where no marine foods are eaten, iodine deficiency is common. It is also common in mountainous regions of the world where food is grown in iodine poor soil. The sicknesses occurred due to deficiencies of iodine in the nutrition are termed iodine deficiency disorders (IDDs). Iodine deficiency create much wider range of disorders, not limited to goitre, started from intrauterine life and extending through childhood to adult life with serious mental and social implications. The spectrum of iodine deficiency disorders include - goitre, hypothyroidism, subnormal intelligence, delay motor milestones, mental deficiency, neuromuscular weakness, endemic cretinism and also intrauterine death. Various studies have documented that in areas with incidence of mild to moderate iodine deficiency disorder, IQ of school children are on average 13 points below, those of children living in areas where there is no iodine deficiency. The addition of iodine to
table salt has largely eliminated this problem in the wealthier nations. However, iodine deficiency still remained a serious public health problem in the developing world.

Recognising the importance of iodine and in greater concern of the public health to ensure the adequate supply of iodine, the central government issued notifications on 17th May 2006 and also passed amendment in prevention of Food Adulteration Rules 1955 that, no person shall vend non-iodised salt for direct human consumption.

Iodine concentration in urine is the most important indicator of person’s nutritional status of iodine, and also key variable to measure the implementation of iodine supplementation in a population. Optimal iodine nourishment is measured by median urinary iodine concentration as per recommendation given by World Health Organization (WHO) and United Nations Children's Fund (UNICEF). Concentration of urinary iodine of 100-199 μg/l in samples from school children and adults suggest adequate intake of iodine. The theory or postulation behind this recommendation was that, only 20% of population was found with <50 μg/l urinary iodine concentration, if threshold level of median urinary iodine concentration of 100 μg/l achieved.

World’s largest goitre belt found in India, that was extending from Kasmir to the Naga hills in the east and even we can say that no state in India entirely free from goitre. Almost 263 district were found endemic in sample survey, in which the prevalence of IDD is >10%. An estimated 71 million persons are suffering from goitre and other iodine deficiency disorders in the entire country.

So, recognising importance of iodine intake for better nourishment and health, Community Medicine Department of Government Medical College, Surat carried out research activity to determine median urinary iodine excretion in urine samples among school going children of Dang district of Gujarat.

Aims and objective

1. To determine median urinary iodine excretion of urine samples.
2. To know status of iodine deficiency based on median urinary iodine excretion

METHODS

A state level IDD laboratory is running by Community Medicine Department of Government Medical College, Surat with the support of State Nutrition cell. Different activities carried out by IDD laboratory are: 1) to organise visits for collection of urine sample from different part of state Gujarat at regular interval, 2) to examine the school going children for iodine deficiency disorders, 3) analysis of urine samples by Sandell-Kolthoff reaction, 4) to document median urinary iodine excretion and 5) reporting to state nutrition cell for further planning and necessary action.

As a part of activity of state IDD laboratory, community based cross sectional study was carried out among purposively selected primary schools of five villages of the Dang district. All students between the age group of 6 to 12 years who were present on the day of visit were included in the study. A total 387 urine samples were collected during the period of August 2015 to September 2016. Data were entered and analysed using Microsoft office excel 2013.

We used epidemiological criteria given by WHO, for evaluating iodine nutrition, based on median urinary iodine excretion in school going children. The frequency below the cut off value of 100, 50 and 20 μg/l correspond to mild, moderate and severe iodine deficiency, respectively. The frequency of population having laboratory result above 200 μg/l indicates having risk of iodine-induced hyperthyroidism.

Adopted from WHO

RESULT

Out of total 387 samples, village Ahwa had median value of 100 μg/l, while all other villages had a median value below 100 μg/l. For total samples, median urinary iodine excretion was 70 μg/l (Table 2).

Urinary iodine excretion ≥100 μg/l, was highest (52.1%) in 12 years of age and lowest (14.3%) in 6 years of age. Gender wise distribution of urinary iodine excretion showed that the proportion of children with urinary iodine excretion <100 μg/l, was 63.4% among male students and 66% among female students (Table 3).

In a figure, it can be easily recognised that adequate intake of iodine (100-199 μg/l) was seen in more than half of study population of Ahwa village (51.6%); in Dhodhalpada, Chikar, Malegav and Sunaniya villages,
about 16.4%, 3.7%, 31.9% and 30.6% study population had adequate iodine nutrition, respectively. Nearly or more than 50% of samples from each villages had insufficient iodine intake revealed by their median urinary iodine excretion of <100 μg/l. Few Urine samples from Malegav and Sunaniya showed more than adequate (200-299 μg/l) and excessive iodine intake (≥300 μg/l) (Figure 1).

Figure 1: Village wise assessment of iodine intake based on median urinary iodine excretion.
Almost 64.4% of children had median urinary iodine excretion of <100 μg/l, suggested iodine deficiency among them. Out of 387 samples, 31.3% of samples had optimal median urinary iodine excretion (100-199 μg/l) and few samples (4.4%) had median urinary iodine excretion of >200 μg/l. According to WHO guideline, if samples with median urinary iodine level <50 μg/l among surveyed population is less than 20%, it suggests adequate iodine nutrition. In this study, proportion of samples with urinary iodine <50 μg/l was 28.5%, which suggest inadequate iodine nutrition among study population (Table 4).

**DISCUSSION**

Urinary iodine concentration is the most suitable biochemical indicator for assessment of iodine nourishment. Insufficient iodine nutrition is a precursor of future increase in range of iodine deficiency disorders. In addition, excessive iodine intake has also adverse health consequences. Optimum median urinary iodine excretion is 100-199 μg/l, which suggest adequate iodine intake. If the person is having adequate iodine intake, chances of occurrence of iodine deficiency disorders would be less. In our study, if we consider a median urinary iodine excretion of total urine samples, it was just 70 μg/l, which suggest mild iodine deficiency in our study population. In contrast, study carried out in Amreli, Jammu and Delhi median urinary iodine excretion is ≥100 μg/l, suggest adequate iodine intake.

Median urinary iodine excretion of ≥100 μg/l was not found in any of the age between 6 to 12 years. Median urinary iodine excretion was lowest in children of 8 years (45 μg/l) age and highest in children aged 12 years (90 μg/l). In our study, about 35.7% of the surveyed population showed median urinary iodine level ≥100 μg/l. In contrast, study carried out in Dahod district of Gujarat, about 57% of surveyed population showed median urinary iodine level ≥100 μg/l. Proportion of children with urinary iodine excretion less than 100 μg/l was lowest (47.9%) among 12 years students and highest (85.7%) in 6 years students where as in Dahod study, proportion of children with median urinary iodine excretion <100 μg/l, was lowest in children of 6 years age (36.8%) and highest in children aged 10 years (47.5%).

In this study, about one third (31.3%) of analysed samples showed adequate iodine nutrition. In the study of Dahod, Amreli and Gandhinagar, about 57%, 61% and 78% analysed samples showed adequate iodine nutrition, respectively. In our study, proportion of samples with urinary iodine excretion <50 μg/l was 28.5%, suggestive of inadequate iodine nutrition according to the WHO guideline of “Assessment of iodine deficiency disorders and monitoring their elimination”. In contrast, in the study of Dahod, proportion of samples with urinary iodine excretion <50 μg/l was found to be 15.6%, which is <20%, corresponds to the category of adequate iodine nutrition as per WHO guidelines for monitoring for IDD.

Based on median urinary iodine excretion, among total analysed samples, about 6.5% samples confirmed severe iodine deficiency, 22% samples showed moderate iodine deficiency & about 36% samples indicated mild iodine deficiency. In the study carried out in Amreli, about 5.95% samples endorsed severe iodine deficiency, 6.67% samples indicated moderate iodine deficiency and about 25.95% samples suggested mild iodine deficiency.

Various studies revealed that single urinary iodine measurement is not representative of an individual’s nutritional iodine status. Urinary iodine concentrations are useful, when used in cross sectional epidemiological surveys with appropriate samples size.

**CONCLUSION**

From the finding of this study, it has been noted that about one third (31.3%) of the surveyed population had adequate iodine intake while majority (64.4%) of them had inadequate iodine intake.

**Recommendations**

There is a need of doing a detailed research with adequate sample size which can represent real scenario of iodine nutrition in the Dang District.
Limitations

Only five schools with limited sample size has been included in this study. We have not assessed amount of salt consumption as well as iodine content of the salt.

ACKNOWLEDGEMENTS

We would like to thank State Nutrition Cell of Gujarat for their constant support. We would also like to thank Principals of schools for giving us permission to carry out research. Also, we would like to thank all school children for participation in the study.
