ABSTRACT

“Flouride” mineral is essential for the normal development of bone and teeth. However, its presence in excess of the required limit results in fluorosis of bone (skeletal) and teeth (dental). It is a dominating public health issue in India due to the geographical fluoride belt across numerous states. Dental fluorosis is characterised by the staining and pitting of tooth/teeth. Despite fluoride’s anticariogenic potential, when present in excess amounts, deteriorates aesthetics and cripples the physical, mental and social health of individuals. Numerous government-led initiatives are in place to optimize fluoride levels, unfortunately, with limited coverage and constrained time frame. The overview is an endeavour to assemble the breathing information on dental fluorosis and the obliviousness towards this condition devastating many lives in India. In this manner, stressing on the squeezing need of educational and dental treatment mediations alongside rebuilding of defluoridation programs across the nation.

Keywords: Fluoride, Fluorosis, Burden, Defluoridation

INTRODUCTION

In Indian society, oral health continues to be disregarded in contrast to systemic wellbeing.¹ Oral diseases are typically widespread in heterogeneous populations and disproportionate society, especially among the economically-strained masses. An enormous chunk of the population lack access to any kind of dental care due to the exiguous public understanding of the determinants of oral health, extensive presence of oral diseases and meagre oral health services in the past.²

Periodontal diseases, dental caries, malocclusion and oral cancer are dental conditions prevalent in India but less significance has been given to Fluorosis and its adverse effects on the population, which poses a serious threat.³ Fluorosis is a dominating public health issue in 24 countries; including India, the reason being the geographical fluoride belt in which India lies.⁴

FLUOROSIS

Uncontrolled intake of fluoride primarily through drinking water, industrial contamination and food products over a prolonged interval can lead to fluorosis. According to world health organization specification, typical incentive for fluoride is 1.5mg per litre, with approximately in the range of 0.8 and 1.2 mg per litre in order to augment benefits and curtail damaging effects. Fluoride contamination strikes teeth (dental fluorosis) and bones (skeletal fluorosis) along with long-term excessive exposure induced pain in abdomen, seizures, vomiting and nausea, increased salivary secretion and muscle spasm.⁵⁶(Table 1)

DENTAL FLUOROSIS

Clinically, dental fluorosis is characterised by the staining and pitting of tooth/teeth. In severe cases, entire enamel may also be damaged. The appearances of teeth may be chalky white along with the presence of white, yellow, brown or black spots or streaks on the surface of enamel. It occurs during developmental stages of tooth formation, children subjected to increased fluoride content develop dental fluorosis. Discolouration is evident when the condition is mild, but in severe cases pitting of enamel can be observed. Both, the primary and permanent dentition are affected.

Various fluorosis indices are used to guage the severity of fluorosis. These are Deans Index, The Thylstrup and Fejeskov index, Total tooth surface index (TSIF), Fluorosis risk index (FRI), and non-specific descriptive indices such as Developmental defects of enamel. Deans fluorosis index is the one being usually utilized. However, it has a few limitations. It does not measure fluorosis at different surfaces of tooth and does not focus on the cosmetic significance of the severe fluorosis estimates. To beat such drawbacks, total tooth surface index can be used.

DISPARITIES CAUSED BY DENTAL FLUOROSIS

Complications does arise in the behaviour and psychology of individuals, affected due to escalation and worldwide prevalence of dental fluorosis which has led to dissatisfaction regarding aesthetics and facial appearance in children and adults. Most obvious being the smile, second facial feature noted by people which enhances the attractiveness of the face. Among adolescents, a smile has a profound influence on self-esteem and confidence as they are concerned about their mien. Their mental prosperity and self-regard is disturbed; particularly critical about their appearance, thus, impacting self-contentment and happiness.

Such circumstances lead to grave public health worries with a colossal impact on wellbeing as well as the living condition of an individual. Despite fluoride’s anticariogenic potential, when present in greater amounts it deteriorates aesthetics which in turn impacts the social and biological health where the socio-economically undermined group is at a substantial risk.

DENTAL FLUOROSIS AS A PUBLIC HEALTH BURDEN

Presence of fluoride universally in the atmosphere, soil and water make humans vulnerable to fluoride exposure through intake of fluoride from sources such as food, water and more recently industrial and pharmaceuticals by-products. Hydrofluorosis being the major component amongst all, increased concentration of fluoride in drinking water has led to tens of millions of dental fluorosis cases throughout the world addressing it as a public health concern.

Fluorosis is an Endemic grappling India since 1937. Approximately 19 states with 230 districts of India enduring with dental and skeletal fluorosis. (Table 2) The seriousness of the condition can be assessed with the help of data giving an estimate of around more than one lakh villages and over 10 million people experience the ailment because of water with high fluoride content.

In India, fluorosis as a public health problem is alarming, with around two-third states being fluoride endemic. The geographical fluoride belt and location of India comprises of rocks and in areas with high fluoride substance or soil. Inevitable leaching of fluoride causes an overabundant fluoride level in groundwater. Drinking water being the primary dietary source of fluoride, it affects a large section of the population.

A cross-sectional assessment conducted on Dental fluorosis and Oral health status of 2400 school-going youngsters in the age group of 13-15 years of Chikkaballapur district, Karnataka state reported the estimated prevalence of dental fluorosis of around 41.1%. Subsequently inferred that the oral health of the individuals was poor and high pervasiveness of fluorosis.
A comparable report on Dental Fluorosis among school children including chemical analysis of potable water sources in Adpalli PHC, Mulchera, Gadchiroli, Maharashtra, India provided information from various areas. It exposed the dental fluorosis to be highest as 76.62% in one district (Kalinagar) descending to 39.25% in another district (Gandhinagar). It was concluded that the psychological and cosmetic impact of dental fluorosis was evident among the population affected by it. 35

Another evaluation directed on the prevalence of dental fluorosis and associated risk factors in Bagalkot District Karnataka India uncovered comparable data addressing drinking water as the essential cause of dental fluorosis, with malnourished children exhibiting a severe form of fluorosis. 36

An observational study on the prevalence of dental fluorosis among adolescents in schools of Greater Noida, Uttar Pradesh concluded that water consumed from hand pumps by a majority of the population is amalgamated with the condition of dental fluorosis although it was discovered that here the issue can be considered as of medium public health concern as the observed Community fluoride Index was 1.7. They examined a total of 1318 school children of which 278 were reported with varying degree of dental fluorosis. 37

Another study on the prevalence and severity of dental fluorosis among school children in a Northern hilly state of India reported the presence of cases of dental fluorosis in Himachal Pradesh. Although during the time of the study, the prevalence varied between 1.5-7% in different districts, an earnest need to address dental problems at the earliest was suggested because the water supply (treated water) to a hilly state is difficult or interruptive forcing people to consume water from natural sources. Thus, compounding the possibility of consuming fluoridated water. 38

An investigation revealed the prevalence of dental fluorosis and dental caries in association with high levels of drinking water fluoride content in a district of Gujarat, India; reported the prevalence of dental fluorosis as 49.26%. Their study revealed that the likelihood of developing fluorosis was higher in the areas with high fluoride content in drinking water. Moreover, it was observed that progress of fluorosis was more as time traversed. 39

In a study conducted in Davangere, it was observed that dental fluorosis was severe when the concentration of fluoride in drinking water increased. Around 69.4% of study subjects presented fluorosis. In water suitable for drinking a level of 0.74 ppm fluoride was found to be responsible for objectionable dental fluorosis. The study indicated that among school children in Davangere district dental fluorosis was a major dental public health concern. 40

Ramesh M et al conducted a study in Salem district on the prevalence of dental fluorosis and its associated factors in Salem District stated that dental fluorosis was reportedly high amongst children the level of fluoride in water was between 0-3ppm. Moreover, it was noticeable that the appearance of fluorosis was proportional with duration for which people had been residing at places with high fluoride content in water. 31

The prevalence of dental fluorosis in relation to different fluoride levels in drinking water among school going children in Sarada Tehsil of Udaipur district was estimated. The prevalence of dental fluorosis was revealed to be 69.84% in the city. Study findings also supported the previous conclusions that an increase in dental fluorosis cases with increase in the fluoride content of water from 0.8-4.1ppm. A strong positive correlation was evident between Community fluoride index (CFI) and fluoride content of drinking water as CFI parameters increased with rising concentration of fluoride in drinking waters. 42

INTERVENTIONS TO MITIGATE FLUOROSIS

The treatment for dental fluorosis is extensive and expensive as well as time consuming. Not easily accessible to the rural population. Lack of sustainable treatment options pave way for interventional and preventory approach. 35 All the studies highlight various government initiated defluoridation programs. Nalgonda technique is one of them where defluoridation is accomplished by contact precipitation using bone charcoal. Also, incorporation of health education regarding appropriate use of fluorides is recommended to spread awareness regarding the etiology and prevention of dental fluorosis. In fluoride affected territories, mother’s ought to be encouraged to breastfeed as fluoride concentration is low in breast milk. Supply of safe drinking water through pipe lines with regulated fluoride content is imperative to ensure its prevention. 34

The Indian government has sincerely attempted to curb the situation. Numerous government-initiated interventions such as Nalgonda technology-based treatment plan, along with UNICEF smaller defluoridation units for families have been introduced; regional surface water-based pipelines and reverse osmosis plants have been placed. National programme for prevention and control of fluorosis (NPPCF) is also an initiative from the government. However, on critically analysing the situation we can say that although these interventions were fruitful, they worked for very short time frame with limited coverage and could not deliver impacts that could last longer. Essentially because of lack of constant attention to these services and absence of focus on exploring long-term solutions to the problem. 35 Also, lack of awareness and food and dietary habits in schools are considered to be responsible for the condition. 36 Thus, stressing the need for interventions in the form of awareness/educational programs.
CONCLUSION

In light of the reliable and consistent findings from various studies on dental fluorosis, it could be reasoned that dental fluorosis is an endemic grappling a huge segment of the country. It deteriorates the physical and psychological well-being of the individuals. Therefore, it ought to be regarded as a public health issue calling for immediate measures to curb it at the earliest.

Finally, to summarize, the various factors contributing to the distribution of dental fluorosis and resultant inequality in health can be enumerated as presence of fluoride in the drinking water beyond the safe limits (>1.5 mg/l); inaccessible treated water to the households thus forcing the residents to drink water/ use water for cooking purposes from the natural sources rich in fluoride; interventional programs with short-term goals; insufficient number of defluoridation programs and unsatisfactory maintenance. Scarce information regarding such programs and their benefit’s outreach; deficient awareness among the population regarding the etiology and various sources of fluoride (drinking water, water used for cooking, food intake, early signs of fluorosis, geographic fluoride belt); Most significantly, lack of proactive response of the government to identify and eliminate the public health problem of dental fluorosis on a large scale in the form of awareness campaigns, defluoridation programs and dental treatment camps.
